# **1230 MODEX**

Many well-known cryptographic operations require modular exponentiation. That is, given integers x, y and n, compute  $x^y \mod n$ . In this question, you are tasked to program an efficient way to execute this calculation.

# Input

The input consists of a line containing the number c of datasets, followed by c datasets, followed by a line containing the number '0'.

Each dataset consists of a single line containing three positive integers, x, y, and n, separated by blanks. You can assume that 1 < x,  $n < 2^{15} = 32768$ , and  $0 < y < 2^{31} = 2147483648$ .

#### Output

The output consists of one line for each dataset. The *i*-th line contains a single positive integer z such that

 $z = x^y \mod n$ 

for the numbers x, y, z given in the *i*-th input dataset.

## Sample Input

```
2
2 3 5
2 2147483647 13
0
```

### **Sample Output**

3 11
