# 13280 Substring Sorting

You are given a string, S (containing only lower-case letters). Next you are given some queries. The queries are of the form:

• *K M* 

This means that you need to find the *M*-th (1-based) substring from the list of sorted distinct substrings of *S* which has length exactly equal to *K*. For example, say S = "abdcabdc" and we are processing the query K = 4, M = 2, that means we are looking for substrings of length 4. They are:

- 1. abdc
- 2. bdca
- 3. dcab
- 4. cabd
- 5. abdc

Since we are looking for distinct substrings, the second "abdc" will be ignored. Now if we sort them the substrings will look like:

- 1. abdc
- 2. bdca
- 3. cabd
- 4. dcab

So for M = 2, the output would be "bdca". However for K = 4 and M = 4, the output would be "dcab". But you don't need to output the actual string. Rather just output the starting index (0-based) of the output string. If there are multiple possible answer, then output the lowest one. So for K = 4 and M = 1 (output string "abdc"), you can see that it can be found in two different starting indices, 0 and 4. As 0 is lowest, so you need to output '0'.

#### Input

First line will contain one integer, T ( $T \le 10$ ), number of test cases. Each case starts with a line containing S ( $1 \le |S| \le 100000$ ). Next line will contain Q ( $1 \le Q \le 100000$ ), number of queries. Each query will contain two integers K and M ( $1 \le K \le |S|$ ,  $1 \le M \le 100000$ ) in a line.

#### Output

For each query, output the starting index (0-based) of the desired substring. If there is no answer, then output 'Not found'. See sample for clarification.

## Sample Input

### 1

- abdcabdc
- 13 1 1
- 1 2
- 13
- 14
- 15
- 2 1
- 2 2
- 23 24
- 2 5
- 4 2
- 44
- 45

## Sample Output

0 1 3 2 Not found 0 1 3 2 Not found 1 2 Not found 1 2 Not found
